Soil *Pseudomonas* species, which thrive on lignin derivatives, are widely explored for biotechnology applications in lignin valorization. However, how the native metabolism coordinates phenolic carbon processing with required cofactor generation remains poorly understood. Here, we achieve quantitative understanding of this metabolic balance through a detailed multi-omics investigation of *Pseudomonas putida* KT2440 grown on four common phenolic acid substrates: ferulate, *p*-coumarate, vanillate, and 4-hydroxybenzoate. Relative to succinate, proteomics reveals > 140-fold increase in transport and catabolic proteins for aromatics, but metabolomics identifies bottlenecks in initial catabolism to maintain favorable cellular energy charge, which is compromised in mutants with resolved bottlenecks. Up to 30-fold increase in pyruvate carboxylase and glyoxylate shunt proteins implies a metabolic remodeling confirmed by kinetic <sup>13</sup>C-metabolomics. Quantitative analysis by <sup>13</sup>C-fluxomics demonstrates coupling of this remodeling with cofactor production. Specifically, anaplerotic carbon recycling through pyruvate carboxylase promotes tricarboxylic acid cycle fluxes to generate 50–60% NADPH yield and 60–80% NADH yield, resulting in up to 6-fold greater ATP surplus than with succinate metabolism; the glyoxylate shunt sustains cataplerotic flux through malic enzyme for the remaining NADPH yield. This quantitative blueprint affords cofactor imbalance predictions in proposed engineering of key metabolic nodes in lignin valorization pathways.

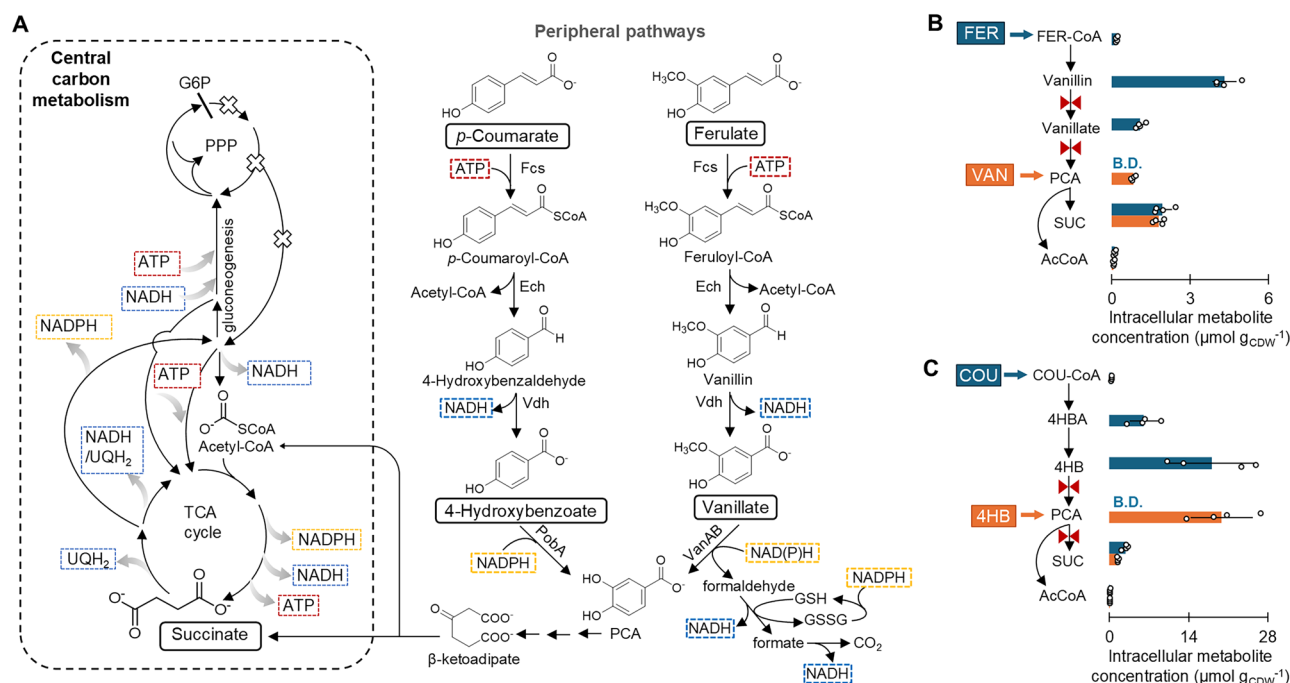

Lignin, a structural polymer in plant biomass that is considered the second most abundant biopolymer after cellulose, represents an important renewable carbon source<sup>1</sup>. Chemical depolymerization of lignin generates various phenolic acid compounds, which can be used as feedstocks for bioproduction of valuable chemicals<sup>2–4</sup>. These lignin-related phenolic acid structures include hydroxybenzoates (4-hydroxybenzoate, vanillate, gallate, and syringate) and hydroxycinnamates (*p*-coumarate and ferulate)<sup>5</sup>. Soil *Pseudomonas* species have native metabolic capabilities to process benzoate, 4-hydroxybenzoate (4HB), vanillate (VAN), gallate, *p*-coumarate (COU), and ferulate (FER)<sup>6</sup>. Of particular interest is *Pseudomonas putida* KT2440, which is extensively explored as a chassis for biotechnology<sup>7–11</sup>, including notably the bio-conversion of lignin-derived aromatics<sup>12,13</sup>. Encoded in *P. putida* KT2440 are pathways for the catabolism of hydroxybenzoates and hydroxycinnamates involving *ortho*-cleavage of the intermediate

protocatechuate (PCA) through  $\beta$ -ketoadipate to generate carbon influx into the tricarboxylic acid (TCA) cycle in the central carbon metabolism<sup>6</sup> (Fig. 1A). In the peripheral pathways upstream of  $\beta$ -ketoadipate, the uptake and catabolism of hydroxycinnamates (COU and FER) and hydroxybenzoates (4HB and VAN) to PCA are catalyzed by a series of enzymes with distinct cofactor specificities<sup>6,13–17</sup> (Fig. 1A). Previous metabolic engineering of *P. putida* targeted directing carbon influx from phenolic carbons from initial catabolism towards desired products such as PCA, vanillin,  $\beta$ -ketoadipate, muconic acid, pyridine 2,4-dicarboxylic acid, adipic acid, indigoidine, free fatty acids and polyhydroxyalkanoates<sup>18–31</sup>. Metabolic bottlenecks, which were inferred from extracellular accumulation of VAN in FER-fed cells or of 4HB in COU-fed cells<sup>21,29,30,32–34</sup>, could not be overcome completely via genetic engineering due to cofactor deficiency<sup>21,30,32</sup>. Therefore, metabolic engineering to enhance phenolic carbon conversion must address

Data in (**B**, **C**) are shown as mean ± standard deviation of four independent biological replicates (*n* = 4).

appropriate cofactor supply. However, largely lacking is a quantitative understanding of how the native metabolic network in *P. putida* KT2440 couples carbon fluxes from phenolic acid structures with required cofactor production.

Metabolic flux modeling or fluxomics constrained by <sup>13</sup>C-metabolomics data provides quantitative analysis of carbon fluxes<sup>35–40</sup>. Previous <sup>13</sup>C-fluxomics studies of *P. putida* focused on glycolytic metabolism for sugars (i.e., glucose, xylose) or gluconeogenic metabolism for succinate (SUC)<sup>41–51</sup>. The only two fluxomics studies of aromatic carbon metabolism in *P. putida*, for benzoate alone or with glucose as a co-substrate<sup>41,52</sup>, both illustrated the activation of the glyoxylate shunt, which conserved carbon by channeling isocitrate away from the canonical decarboxylation steps in the TCA cycle. Flux through the glyoxylate shunt can feed into malic enzyme for NADPH generation, or malate dehydrogenase, for NADH or ubiquinol generation. Interestingly, for benzoate catabolism, the flux through malate dehydrogenase was either 3-fold higher than the flux through malic enzyme or there was only flux through malate dehydrogenase, both of which would be advantageous to satisfy the NADH demand for benzoate catabolism through the catechol pathway in *P. putida*<sup>41,52</sup>. For the catabolism of hydroxybenzoate and hydroxycinnamate structures, which is funneled through PCA instead of catechol, it remains unknown how metabolic fluxes would be partitioned in *P. putida* to optimize the catabolic pathways with cofactor supply (Fig. 1A).

While ATP in aerobic bacteria is generated primarily through oxidative phosphorylation of NADH produced in glycolysis and the TCA cycle<sup>53</sup>, the supply of NADPH required for biosynthesis and stress tolerance is produced from different metabolic routes. During growth on glucose, NADPH production in *P. putida* includes the important involvement of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase in the oxidative pentose phosphate pathway (oxPPP)<sup>44,47</sup>. However, minimal to no

flux through oxPPP was reported during growth on two gluconeogenic substrates (SUC or benzoate)<sup>48,52</sup>. Instead, gluconeogenic metabolism in *P. putida* was reported to rely on high flux through isocitrate dehydrogenase and malic enzyme in the TCA cycle to produce NADPH, and on transhydrogenase reactions to generate NADPH from excess NADH pool<sup>48</sup>. Whether *P. putida* would rely on similar metabolic routing or energetic bypass for NADPH production during phenolic acid utilization remains to be elucidated.

The cataplerotic and anaplerotic nodes, which distribute respectively carbon fluxes from the TCA cycle to gluconeogenesis and from lower glycolysis to the TCA cycle<sup>54</sup>, have implications for cofactor balance (Fig. 1A). In the cataplerotic direction, due to lack of phosphoenolpyruvate (PEP) carboxykinase for the decarboxylation of oxaloacetate (OAA) to PEP<sup>55</sup>, *P. putida* KT2440 must rely on either malic enzyme to convert malate to pyruvate with NADPH production or OAA decarboxylase to convert OAA to pyruvate with no cofactor involved<sup>56</sup>. In the anaplerotic direction, pyruvate carboxylation to OAA consumes ATP, while PEP carboxylation to OAA has no cofactor input<sup>56</sup>. It remains unclear how *P. putida* KT2440 would distribute carbon fluxes between cataplerosis and anaplerosis to meet the demand for reducing equivalents and energy required for phenolic carbon catabolism.

Here, our central hypothesis was that remodeling of metabolic nodes into and within the TCA cycle by *P. putida* KT2440 would establish the fluxes of NAD(P)H and ATP to satisfy the cofactor demands in the *p*-coumaroyl and coniferyl pathways (Fig. 1A). We tested our hypothesis by employing genetic engineering, metabolomics profiling, whole-cell proteomics, kinetic <sup>13</sup>C-metabolomics, and <sup>13</sup>C-fluxomics during feeding of *P. putida* KT2440 on FER, COU, VAN, or 4HB as the sole carbon source, compared to SUC as non-aromatic substrate reference. First, using quantitative metabolomics for cofactor profiling in wild-type and mutant strains,

we investigated how the cellular energy state would be influenced by alterations in the aromatic carbon influx due to overexpression of key bottleneck-relevant genes. Second, to elucidate the metabolic network that underlies the cellular energy state, we profiled protein levels to identify metabolic remodeling nodes and verify these nodes using kinetic  $^{13}\text{C}$ -profiling in metabolites coupled with  $^{13}\text{C}$ -carbon mapping. Third, we integrated the proteomics and  $^{13}\text{C}$ -metabolomics data to perform  $^{13}\text{C}$ -fluxomics to map quantitatively carbon fluxes throughout the metabolic network. Fourth, we leveraged the quantitative flux analysis to determine production and consumption rates of cofactors and evaluate metabolic flux controls on cofactor maintenance during conversion of the different lignin-derived phenolic acid compounds. This research provides the first quantitative mapping of the relationship between carbon metabolism and energy metabolism in *P. putida* KT2440 utilizing different hydroxycinnamate and hydroxybenzoate substrates, thereby guiding the predictions of cofactor balancing required during engineering of metabolic pathways for lignin valorization.

## Results

### Favorable cellular energy balance is sustained despite bottleneck nodes in native catabolism

Bottlenecks were proposed previously at three nodes in initial phenolic acid catabolism, based on extracellular metabolic overflow in exponentially growing cells: the VanAB node in the coniferyl branch<sup>21,29</sup>, the PcbA node in the *p*-coumaroyl branch<sup>21,30,32</sup>, and the PcaHG node downstream of both branches<sup>29</sup> (Fig. 1A). Here, we obtained direct evidence using intracellular metabolomics analysis and  $^{13}\text{C}$  kinetic isotopic profiling of exponentially growing cells to confirm the three reported bottlenecks (at VanAB, PcbA, and PcaHG nodes) and identify one additional bottleneck at the Vdh node (Fig. 1B, C; Supplementary Information (SI), Fig. S1).

In the coniferyl branch, bottleneck at the Vdh node was characterized by a 20-fold and 4-fold higher intracellular vanillin concentration ( $4.3 \pm 0.5 \mu\text{mol g}_{\text{CDW}}^{-1}$ ) relative to its precursor feruloyl-CoA ( $0.2 \pm 0.03 \mu\text{mol g}_{\text{CDW}}^{-1}$ ) and its downstream metabolite vanillate ( $1.1 \pm 0.2 \mu\text{mol g}_{\text{CDW}}^{-1}$ ), respectively; further downstream, PCA was below the detection limit of  $0.1 \mu\text{M}$  (Fig. 1B). This bottleneck was further illustrated by 50% lower incorporation of  $^{13}\text{C}$ -FER in vanillin compared to feruloyl-CoA within 1 min of isotope switch ( $P < 0.05$ ) (SI, Fig. S1). Even with VAN as the direct carbon source, PCA level remained low ( $0.8 \pm 0.1 \mu\text{mol g}_{\text{CDW}}^{-1}$ ), in accordance with inefficient VAN conversion to intracellular PCA by VanAB (Fig. 1B). In the *p*-coumaroyl branch, in line with the reported bottleneck node at PcbA<sup>21,30,32</sup>, there was a high intracellular 4HB level ( $18.1 \pm 7.6 \mu\text{mol g}_{\text{CDW}}^{-1}$ ) during COU catabolism, while 4-hydroxybenzaldehyde (4HBA) level was 67% lower ( $P < 0.05$ ) and PCA level was below the detection limit (Fig. 1C). Furthermore, consistent with this bottleneck at PcbA, there was 31% smaller fraction of  $^{13}\text{C}$ -COU carbons in 4HB than in 4HBA within 1 min ( $P < 0.01$ ) (SI, Fig. S1). During growth on 4HB, PCA accumulated ( $19.8 \pm 5.4 \mu\text{mol g}_{\text{CDW}}^{-1}$ ), in accordance with the reported bottleneck at PcaHG (Fig. 1C)<sup>29</sup>.

Towards resolving the bottlenecks in the coniferyl branch, we constructed four mutant strains: RW124 with *vanAB* overexpression, RW125 with combined overexpression of *vanAB* and *pcaHG*, RW127 with overexpression of *vdh*, and RW126 with stacked overexpression of *vdh*, *vanAB*, and *pcaHG* (Fig. 2A). Overexpression of *vdh* (strain RW127) led to an 80% decrease in vanillin and a 24-fold increase in VAN ( $P < 0.001$ ), indicating that addressing the bottleneck at Vdh triggered a downstream bottleneck at VanAB (Fig. 2B). Compared to metabolite levels in RW127 fed on FER, a decreased VAN level (by 93%,  $P < 0.001$ ) in RW126 indicated simultaneous alleviation of the bottlenecks at both Vdh and VanAB (Fig. 2B). Compared to the wild-type strain grown on VAN, the unchanged intracellular PCA level in RW124 and depletion of PCA (by 83%,  $P < 0.001$ ) in RW125 demonstrated efficient PCA cleavage and thus elimination of the bottleneck at PcaHG during VAN catabolism (Fig. 2C). Cellular energy charge was 25–44% lower in the mutant strains in the coniferyl branch compared to the wild-type strain ( $P < 0.05$ ) (Fig. 2B, C; SI, Table S1).

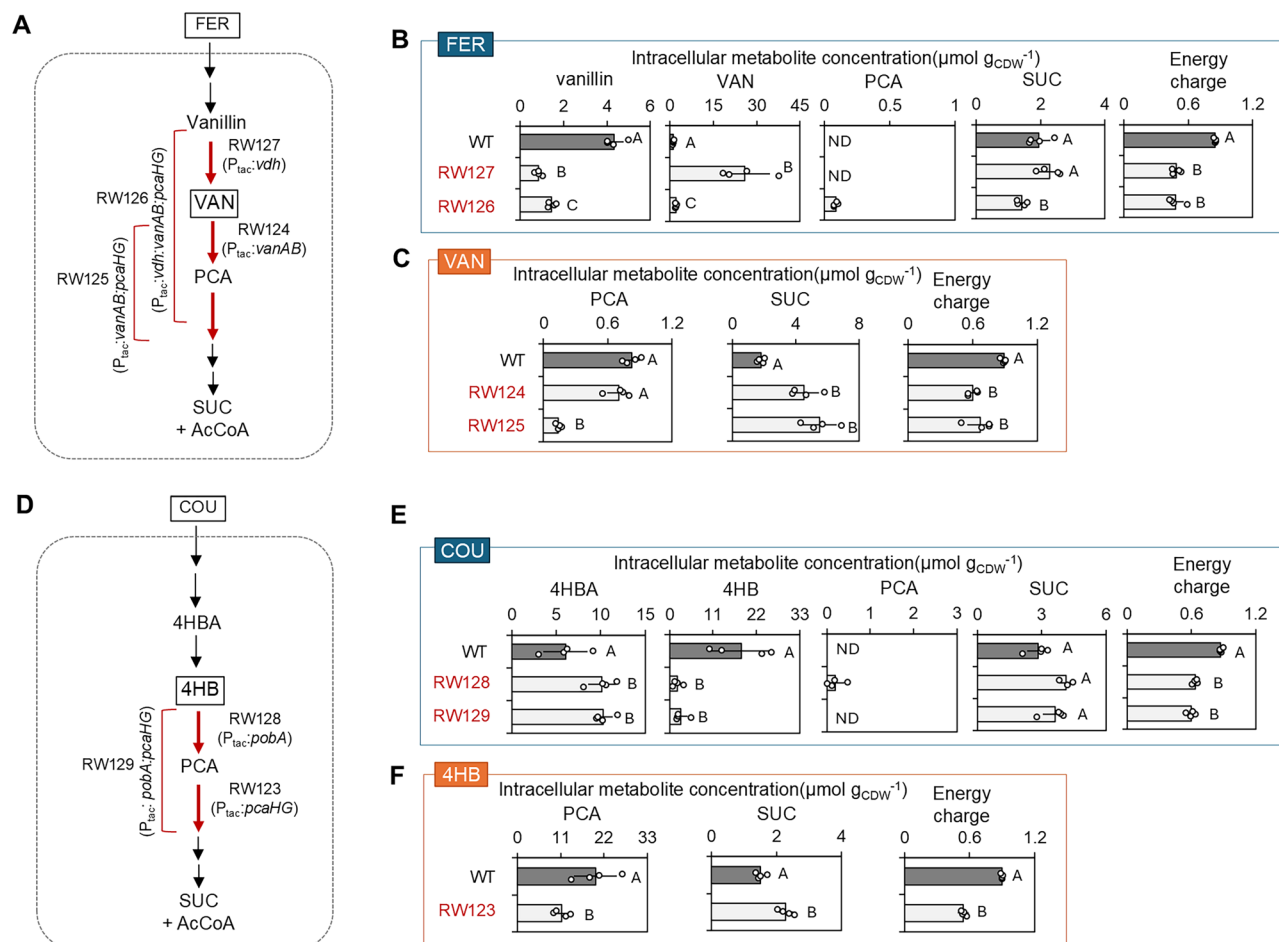

To resolve the bottlenecks in the *p*-coumaroyl branch, we prepared three mutant strains that overexpressed either *pobA* (RW128), *pcaHG* (RW123), or both *pobA* and *pcaHG* (RW129) (Fig. 2D). Compared to the wild-type strain, the bottlenecks were resolved in RW128 and RW123, characterized by a 90% decrease in 4HB during growth on COU and a 50% decrease in PCA during growth on 4HB ( $P < 0.05$ ), respectively (Fig. 2E, F). Similar to the coniferyl branch, the energy charge of the mutants of the *p*-coumaroyl branch was 32–40% lower than in the wild-type strain ( $P < 0.05$ ) (Fig. 2E, F; SI and Table S1).

In sum, alleviation of native metabolite buildups in initial substrate catabolism led to adverse change in the cellular energy charge, thereby implying an interplay between the regulation of phenolic carbon influx and cofactor balance and a potential energy burden caused by gene overexpression<sup>50</sup>. It remains to be investigated whether this metabolic burden could be overcome through alternative genetic engineering approaches, such as tuning of the ribosomal binding site or chromosomal integration. Interestingly, when we compared growth phenotypes of the *P. putida* KT2440 cells on FER, COU, VAN, or 4HB to reported growth phenotype on SUC (a nonaromatic substrate ref. 48), the biomass yield of *P. putida* was similar across all five substrates ( $P = 0.64$ – $0.99$ ), despite the differences in growth and substrate depletion rates (SI, Fig. S2). However, we obtained 25–31% higher energy charge when the wild-type cells were grown on the phenolic substrates compared to growth on SUC ( $P < 0.001$ ) (SI, Fig. S2). These data further implied that carbon influx during phenolic acid assimilation was optimized for a favorable cellular energy charge. Towards understanding the metabolic mechanisms underlying native cofactor balance, we investigated protein levels, metabolite pools, and the network of carbon fluxes during processing of the different phenolic acid compounds.

### Abundances of transporters and specialized enzymes are modulated to adapt to phenolic carbon influx

We obtained whole-cell proteomics data to compare the abundance of proteins involved in membrane transport, the coniferyl branch, the *p*-coumaroyl branch, and the central carbon metabolism in *P. putida* cells fed on each phenolic substrate relative to cells fed on SUC (Fig. 3). For each of the four biological replicates across the five growth substrates, we employed a high-resolution proteomics method to capture over 4300 proteins out of the 5950 total proteins encoded by *P. putida* KT2440, including low-abundance proteins that are typically undetected (SI, Table S2). In agreement with the assignment of HcnK as the common transporter for hydroxycinnamate uptake to both the coniferyl and *p*-coumaroyl branches<sup>13</sup>, abundance of HcnK was 700-fold greater in *P. putida* cells fed with FER or COU relative to SUC (Fig. 3A; SI, Table S3). The HcnK abundance was also 9-fold to 13-fold higher in cells grown on VAN and 4HB relative to SUC (Fig. 3A; SI, Table S3), indicating that the abundance of this transporter was also induced by downstream metabolites in the pathways. For the VAN transporter VanK<sup>13</sup>, its abundance was 830-fold higher in cells fed with VAN or FER compared to SUC (Fig. 3A; SI, Table S3), consistent with the dependence of VanK level on the presence of VAN either as a substrate or as an intermediate in FER catabolism (Fig. 1A). Similarly, the abundance of the 4HB transporter PcaK was increased to similar extent (>140-fold) during growth across all four phenolic substrates compared to growth on SUC, in accordance with PcaK serving also as a transporter of PCA<sup>13,16</sup>, a common downstream intermediate in both the coniferyl and *p*-coumaroyl branches (Fig. 3A; SI, Table S3).

After substrate uptake, a series of cofactor-dependent enzymes are involved in the initial catabolism (Fig. 3A). Compared to SUC-fed cells, the abundances of Fcs, Ech, and Vdh, which collectively catalyze the conversion of FER to VAN or COU to 4HB, were up to 590-fold higher in cells fed on FER or COU, but remained unchanged in cells grown on VAN or 4HB (Fig. 3A; SI, Table S3). The abundance of VanAB, which catalyzes O-demethylation of VAN to produce PCA and formaldehyde, was up to 2700-fold higher in cells grown on FER or VAN compared to SUC; the corresponding increase during feeding on COU and 4HB was 60-fold (Fig. 3A;

**Fig. 2 | Resolved bottleneck nodes in initial catabolism and unfavorable cellular energy state indicated by decreased energy charge values. A** Targeted nodes in the coniferyl branch for gene overexpression. Intracellular metabolite levels and energy charge in the wild-type and mutant strains during feeding on **B** FER and **C** VAN. **D** Targeted nodes in the *p*-coumaroyl branch for gene overexpression. Intracellular metabolite levels and energy charge in the wild-type and mutant strains during

feeding on **E** COU and **F** 4HB. FER-CoA feruloyl-CoA, COU-CoA *p*-coumaroyl-CoA. In **B**, **C**, and **E**, one-way ANOVA was performed followed by Tukey's HSD post hoc test to determine the significance. In **F**, unpaired *t*-test was performed to evaluate the significance. Statistically significant differences ( $P < 0.05$ ) are denoted by a change in letter. Data in **B**, **C**, **E**, and **F** are shown as mean  $\pm$  standard deviation of four independent biological replicates ( $n = 4$ ).

SI, Table S3). To avoid the accumulation of toxic formaldehyde, *P. putida* can oxidize formaldehyde to CO<sub>2</sub> via formate as an intermediate using formaldehyde dehydrogenase (FrmA, FdhA) and formate dehydrogenase (Fdh, Fmd, Fdo) (Fig. 3B; SI, Table S3)<sup>57</sup>. Accordingly, relative to SUC-grown cells, the abundance of FrmA and FdhD was up to 40-fold higher in cells grown on FER or VAN, but remained unchanged in cells grown on COU or 4HB (Fig. 3B; SI, Table S3). Related to stress tolerance strategies<sup>58,59</sup>, abundance of TtgABC efflux pump was 3-fold higher in VAN-grown cells compared to SUC-fed cells (SI, Table S3), suggesting its involvement in formaldehyde tolerance. For the conversion of 4HB to PCA, the abundance of PobA was up to 3100-fold higher during feeding on COU or 4HB relative to SUC feeding; the corresponding change was up to 550-fold higher in cells grown on FER or VAN (Fig. 3A; SI, Table S3).

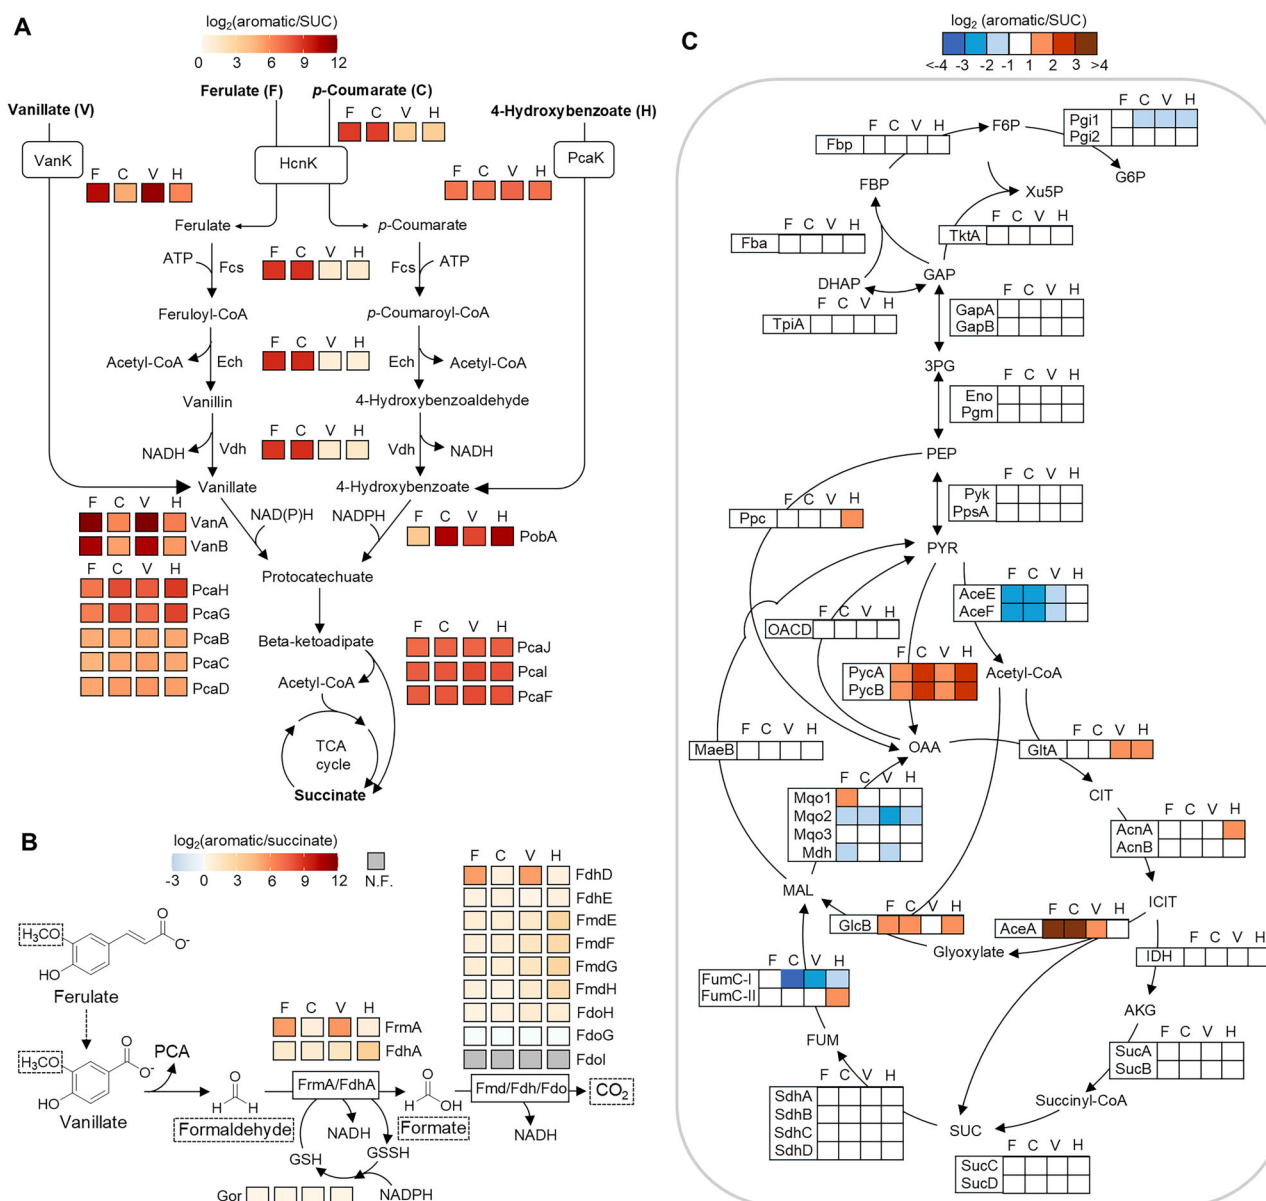

Taken together, the increased abundance of the initial catabolic enzymes across all substrates implied co-regulation in the utilization of the different phenolic acid substrates. In fact, compared to growth on SUC, the levels of enzymes (PcaHGBCDJIF) involved in the *ortho*-cleavage of PCA via the  $\beta$ -ketoadipate pathway showed 40-fold to 500-fold increase during growth on the four phenolic substrates (Fig. 3A; SI, Table S3). Importantly, the  $\beta$ -ketoadipate pathway generates SUC and acetyl-CoA as additional carbon influxes into the TCA cycle compared to metabolism of SUC alone (Fig. 3A). Next, we evaluated changes in protein abundances in the central carbon metabolism (Fig. 3C).

### Fluxes through $\beta$ -ketoadipate pathway and enhanced anaplerosis promote carbon retention in the TCA cycle

Only three nodes in central carbon metabolism showed greater than 2-fold changes in protein abundances during growth on the phenolic substrates relative to growth on SUC. First, we observed 2.5-fold to 6-fold more abundant pyruvate carboxylase (Pyc), which catalyzes the anaplerotic reaction of pyruvate carboxylation to OAA, while there was little to no change (<2-fold) in the abundance of phosphoenolpyruvate carboxylase (Ppc), which catalyzes the other anaplerotic reaction of PEP carboxylation, suggesting a dominant role of Pyc during growth on the phenolic acid compounds (Fig. 3C; SI, Table S3). Second, the two enzymes (AceA and GlcB) involved in the glyoxylate shunt were 2-fold to 30-fold more abundant (Fig. 3C; SI, Table S3). Third, the abundance of AceE and AceF, which catalyze pyruvate to acetyl-CoA, was up to 6-fold lower in cells fed on FER or COU, potentially due to the additional influx of acetyl-CoA from the hydroxycinnamate substrates. To corroborate the metabolic remodeling inferred from the proteomics data, we performed kinetic <sup>13</sup>C-profiling of *P. putida* KT2440 cells switched from unlabeled substrates to 50% phenyl-<sup>13</sup>C<sub>6</sub>-FER, phenyl-<sup>13</sup>C<sub>6</sub>-COU, phenyl-<sup>13</sup>C<sub>6</sub>-VAN, phenyl-<sup>13</sup>C<sub>6</sub>-4HB, or U<sup>13</sup>C<sub>4</sub>-SUC (Fig. 4A).

The kinetic <sup>13</sup>C-profiling of intracellular metabolites captured the assimilation of substrate carbons in specific metabolic pathways. The slower incorporation of <sup>13</sup>C into the coniferyl branch relative to the *p*-coumaroyl

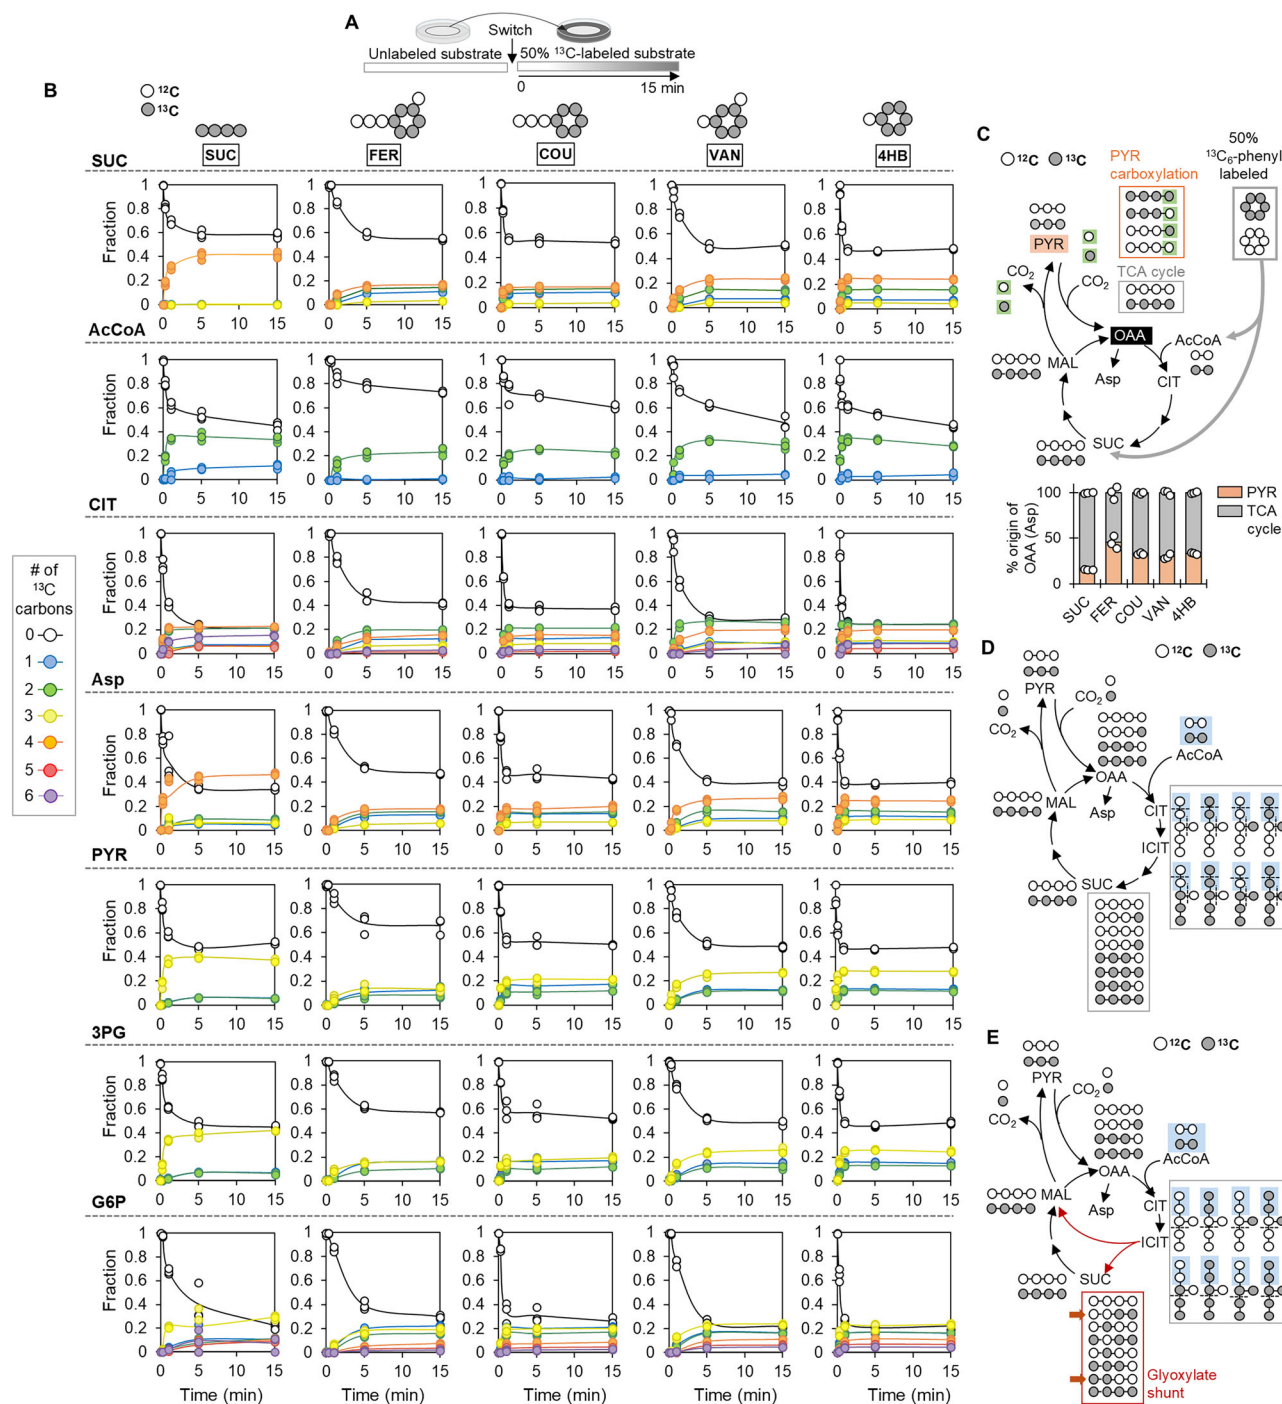

**Fig. 3 | Co-regulation of initial catabolism and selective remodeling nodes in central carbon metabolism.**  $\log_2$  fold change in protein abundance in **A** the peripheral pathways, **B** formaldehyde oxidation pathway, and **C** central carbon metabolism during feeding on each phenolic acid substrate compared to SUC. In **B**, Only NADH was reported to be produced during formaldehyde and formate oxidation based on previous studies<sup>92,93</sup>. HcnK hydroxycinnamic acid transporter, VanK vanillate transporter, PcaK 4-hydroxybenzoate/protocatechuate transporter, Fcs feruloyl-CoA synthase, Ech feruloyl-CoA hydratase-lyase, Vdh vanillin dehydrogenase, VanAB vanillate O-demethylase, Poba 4-hydroxybenzoate 3-monooxygenase, PcaH protocatechuate 3,4-dioxygenase beta chain, PcaG protocatechuate 3,4-dioxygenase alpha chain, PcaC 4-carboxymuconolactone decarboxylase, PcaB 3-carboxy-cis-muconate cycloisomerase, PcaD 3-oxoadipate enol-lactonase, PcaI 3-oxoadipate CoA-transferase, PcaF betaketoadipyl-CoA thiolase, FrmA formaldehyde dehydrogenase, FdhA formaldehyde dehydrogenase, FmdEFGH formate dehydrogenase, FdhDE formate dehydrogenase, FdoHGI formate dehydrogenase, Gor glutathione reductase, Fbp fructose-1,6-bisphosphatase, Pgi glucose-6-phosphate isomerase, Fba fructose-1,6-bisphosphate aldolase, TktA

Metabolite abbreviations: G6P glucose-6-phosphate, F6P fructose-6-phosphate, FBP fructose-1,6-bisphosphate, Xu5P xylulose-5-phosphate, GAP glyceraldehyde-3-phosphate, DHAP dihydroxyacetone phosphate, 3PG 3-phosphoglycerate, PEP phosphoenolpyruvate, PYR pyruvate, CIT citrate, ICIT isocitrate, AKG alpha-ketoglutarate, FUM fumarate, MAL malate, OAA oxaloacetate. Only NADH is produced during formaldehyde and formate oxidation based on previous studies<sup>92,93</sup>. Data of the protein abundances and metabolite levels from four independent biological replicates ( $n = 4$ ) are provided in SI, Tables S3 and S4. The full dataset of proteomics is provided in Supplementary Data 1.

branch was consistent with up to 58% slower uptake rates of the respective substrates (SI, Figs. S1 and S2). After 1 min, the  $^{13}\text{C}$ -labeled fractions of the intracellular SUC were at up to 24% in cells grown on FER and VAN, but at up to 52% in cells grown on COU and 4HB ( $P < 0.001$ ) (Fig. 4B). The

$^{13}\text{C}$ -labeled fraction of acetyl-CoA in cells grown on the hydroxycinnamates (FER and COU) was up to 50% lower than in cells grown on the hydroxybenzoates (VAN and 4HB) ( $P < 0.05$ ), due to the production of unlabeled acetyl-CoA via Ech-mediated reaction on the hydroxycinnamates (Fig. 4B).

**Fig. 4 | Kinetic  $^{13}\text{C}$ -profiling and carbon mapping of metabolic flux partitioning revealed metabolic remodeling nodes in the central carbon metabolism.**

**A** Schematic illustration of kinetic isotope incorporation experiment using 50%  $^{13}\text{C}$ -labeled substrates. **B** Kinetic  $^{13}\text{C}$ -profiling of central carbon metabolites. **C** Contribution from pyruvate versus malate to the oxaloacetate pool determined by carbon mapping when cells were grown on 50%  $^{13}\text{C}$ -labeled phenolic substrates or SUC. Isotopologues of TCA cycle intermediates predicted by carbon mapping when assuming **D** 100% canonical TCA cycle and **E** 100% glyoxylate shunt. Kinetic

$^{13}\text{C}$ -profiling of dihydroxyacetone phosphate, PEP, alpha-ketoglutarate, and sedoheptulose-7-phosphate are provided in SI, Fig. S5. We presented the data in **B** as individual data points in three independent biological replicates ( $n = 3$ ), some of the data points are invisible due to the highly reproducibility among replicates. Values of individual data points for kinetic  $^{13}\text{C}$ -metabolomics are provided in Supplementary Data 2. Asp aspartate, other abbreviations of metabolites are the same as shown in Fig. 3.

Furthermore, consistent with the additional acetyl-CoA influx from the  $\beta$ -ketoadipate pathway,  $^{13}\text{C}$ -labeled acetyl-CoA was predominantly doubly  $^{13}\text{C}$ -labeled (>90%) during growth on the phenolic substrates (Fig. 4B). Despite similar substrate uptake rates,  $^{13}\text{C}$ -labeled fraction within 15 s was up to 2-fold higher in 4HB-grown cells ( $P < 0.01$ ), confirming exceptionally high TCA cycle flux for 4HB assimilation (Fig. 4B). We further confirmed

metabolic remodeling through carbon mapping combined with  $^{13}\text{C}$ -metabolomics (Fig. 4C–E).

Regarding metabolic remodeling through anaplerosis inferred from changes of Pyc abundance, we determined the relative fraction of OAA derived from pyruvate by tracking triply  $^{13}\text{C}$ -labeled OAA (via aspartate labeling), which would be generated only from the carboxylation of triply

$^{13}\text{C}$ -labeled pyruvate by unlabeled  $\text{CO}_2$  (Fig. 4C). At the plateau of the kinetic  $^{13}\text{C}$  data, we recorded 38% triply  $^{13}\text{C}$ -labeled pyruvate and 6% triply  $^{13}\text{C}$ -labeled aspartate in the SUC-fed cells (Fig. 4B), reflecting that 16% of OAA was derived from pyruvate (Fig. 4C), consistent with previous flux analysis<sup>60</sup>. However, the isotopologue profiling in cells fed on the phenolic substrates revealed 30–45% of OAA derived from pyruvate (Fig. 4C), thus highlighting the increase in Pyc-catalyzed pyruvate carboxylation to OAA (i.e., anaplerosis) implied by the proteomics data.

To verify metabolic remodeling through the glyoxylate shunt, we illustrated carbon mapping for two scenarios. In one scenario, the metabolite SUC generated exclusively through the canonical TCA cycle with no flux through the glyoxylate shunt would result in non-labeled, singly  $^{13}\text{C}$ -labeled, triply  $^{13}\text{C}$ -labeled, and fully  $^{13}\text{C}$ -labeled SUC after one cycle of carbon mapping (Fig. 4D); an additional cycle would generate the same isotopologues (SI, Fig. S4). In another scenario, the glyoxylate shunt in the TCA cycle would generate doubly  $^{13}\text{C}$ -labeled SUC through isocitrate lyase (AceA) (Fig. 4E). Detection of this doubly  $^{13}\text{C}$ -labeled isotopologue only in the cells fed on the phenolic substrates confirmed the activation of the glyoxylate shunt during the metabolism of these substrates (Fig. 4B). Taken collectively, the findings from both the proteomics data and the  $^{13}\text{C}$ -metabolomics data delineated the operational metabolic network for phenolic acid utilization. To gain quantitative insights into the carbon and energy fluxes through the metabolic network, we performed  $^{13}\text{C}$ -fluxomics to obtain the fluxes through the different metabolic reactions and subsequently mapped out the cofactor balancing.

### Remodeling of TCA cycle-associated fluxes sustains required cofactor balancing and ATP surplus

The algorithm for the  $^{13}\text{C}$ -fluxomics of each of the four phenolic acid substrates was constrained by biomass growth rates, substrate depletion rates, metabolite secretion rates, intracellular metabolite levels, and kinetic  $^{13}\text{C}$ -profiling of metabolites (Fig. 5A–D). Relative to SUC metabolism, the phenolic substrates generate influxes of acetyl-CoA from both the aromatic cleavage through the  $\beta$ -ketoacid pathway and the acryl group in the hydroxycinnamates (FER and COU) (Fig. 1A). Consequently, the citrate synthase flux, which combines OAA with acetyl-CoA to form citrate, was up to 2-fold higher for the catabolism of the hydroxycinnamate compounds (FER and COU) than for the catabolism of the hydroxybenzoate compounds (VAN and 4HB) (Fig. 5A–D). Accordingly, citrate and  $\alpha$ -ketoglutarate levels were up to 10-fold and 7-fold higher ( $P < 0.001$ ), respectively, in cells grown on phenolic substrates than on SUC, implying high carbon flux towards the high energy-producing side of the TCA cycle (SI, Table S4). Notably, flux through the glyoxylate shunt was determined to be 2.5-fold to 13-fold higher during metabolism of the hydroxycinnamates than the hydroxybenzoates (Fig. 5A–D), consistent with our proteomics data on the relative abundance of AceA in the glyoxylate shunt during growth on the different types of phenolic acid substrates (Fig. 3C; SI, Table S3).

With respect to the flux remodeling at the cataplerosis-anaplerosis nodes, the cataplerotic flux through malic enzyme was 1.4-fold to 2.5-fold higher during phenolic substrate catabolism compared to SUC catabolism, while there was no flux through OAA decarboxylase (Fig. 5A–D; SI, Fig. S6). In fact, our intracellular metabolomics data revealed that intracellular malate decreased by up to 70% ( $P < 0.05$ ), while PEP and 3-phosphoglycerate (3PG) increased 2-fold to 60-fold ( $P < 0.01$ ) during phenolic substrate utilization, relative to SUC utilization, indicating strong cataplerotic flux from the TCA cycle towards intermediates in gluconeogenesis (SI, Table S4). Informed by the proteomics data, which highlighted up to 6-fold increase in Pyc (pyruvate carboxylase) relative to less than 2-fold increase in Ppc (PEP carboxylase) ( $P < 0.001$ ) (Fig. 5), anaplerotic flux was constrained to occur only via Pyc, involving the carboxylation of pyruvate to OAA, to replenish four-carbon intermediates in the TCA cycle. This pyruvate-to-OAA anaplerotic flux was 7-fold to 20-fold higher during phenolic substrate utilization than SUC utilization (Fig. 5A–D; SI, Fig. S6), in agreement with the 2-fold to 3-fold higher OAA production from

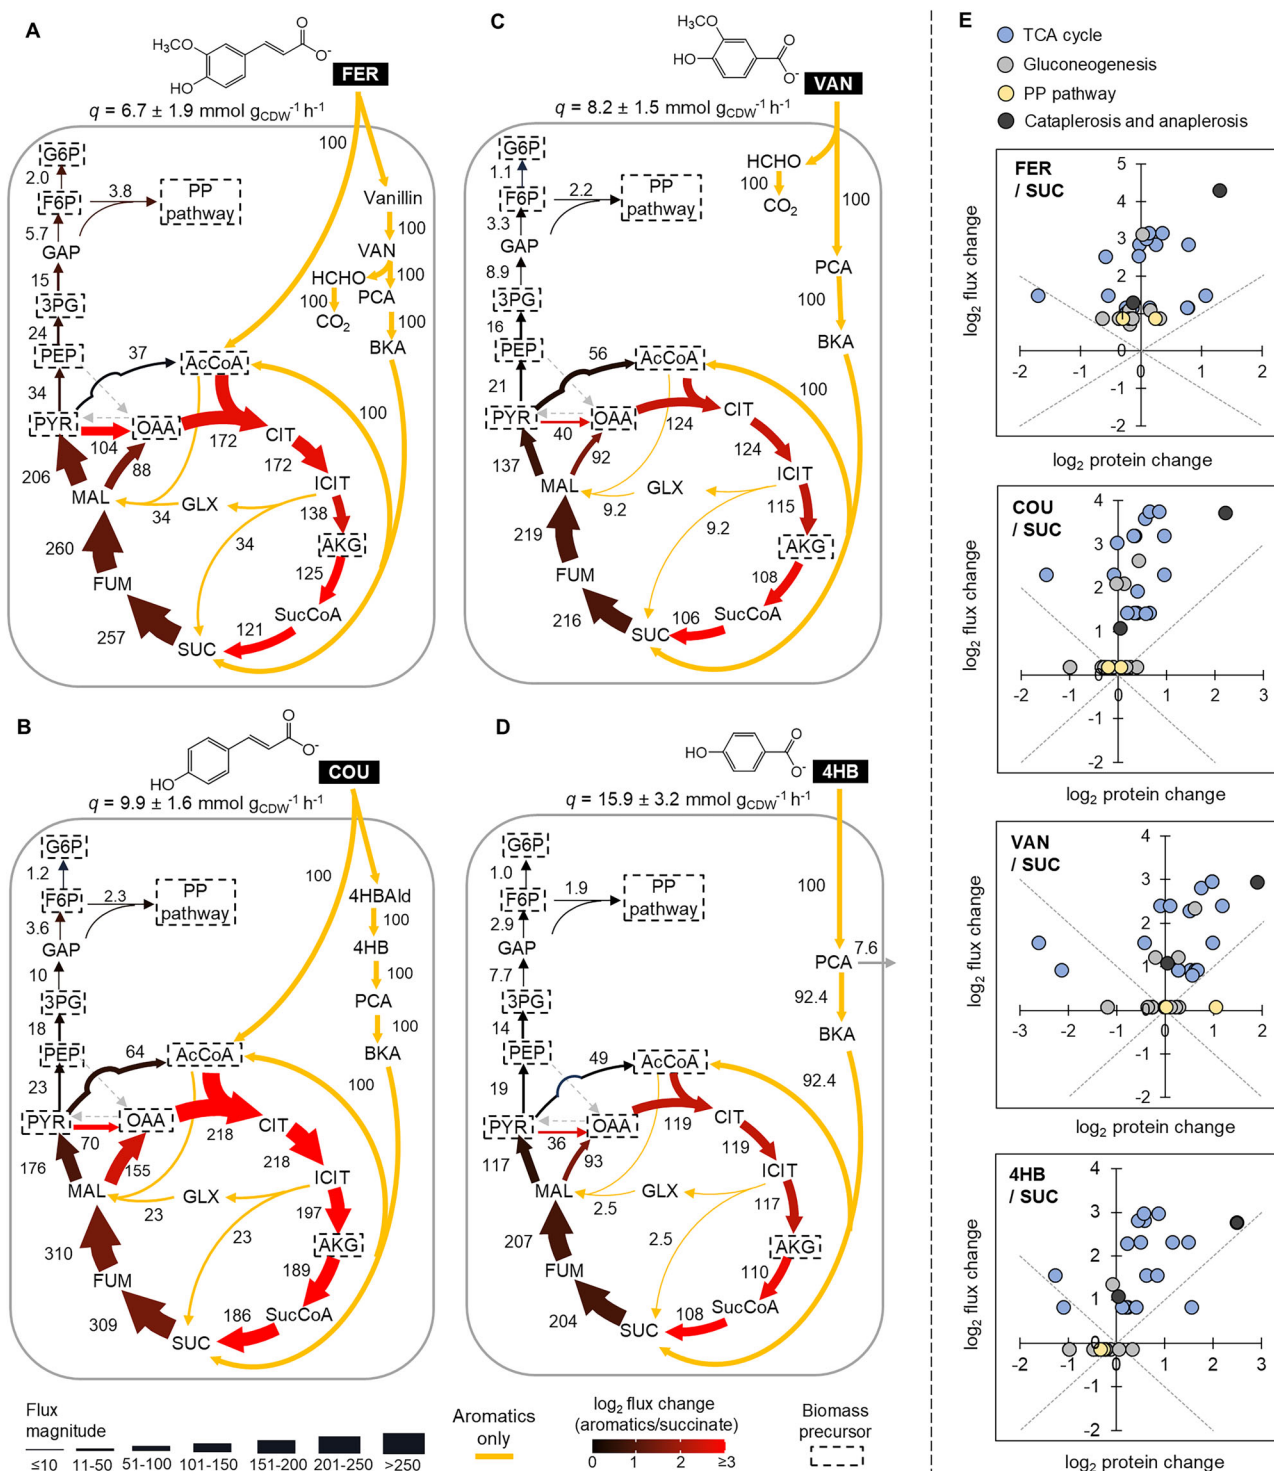

pyruvate influx illustrated by the carbon mapping combined with kinetic  $^{13}\text{C}$ -metabolomics (Fig. 4C). For resolving whether to include flux through pyruvate dehydrogenase, we performed additional  $^{13}\text{C}$ -fluxomics with and without the reaction of pyruvate to acetyl-CoA (SI, Table S5). The model fit was not statistically acceptable when we deactivated this reaction in FER and COU (SI, Table S5), suggesting possible sufficient protein abundance to support flux or post-translational regulation<sup>41,61</sup>. Therefore, pyruvate dehydrogenase was considered active during the phenolic substrate catabolism despite the observed decrease in the protein abundance (Fig. 3C).

We compared our high-resolution  $^{13}\text{C}$ -fluxomics of the metabolic network with the widely used approach of flux balance analysis (FBA), which is based only on substrate uptake and biomass growth rates and is thus derived from a low-resolution algorithm (Fig. 5A–D, Supplementary Data 4). In both  $^{13}\text{C}$ -fluxomics and FBA, sustenance of high TCA cycle flux was prioritized over gluconeogenic flux during phenolic substrate catabolism (Fig. 5A–D; Supplementary Data 4). Specifically, the  $^{13}\text{C}$ -fluxomics predicted that although the cataplerotic flux through malic enzyme (i.e., from malate to pyruvate) was substantial (60–80% of the carbon influx to malate), only 13–16% of this cataplerotic flux was invested towards gluconeogenic flux because 69–77% was recycled back to the TCA cycle via both pyruvate carboxylase (to replenish OAA) and pyruvate dehydrogenase (to generate acetyl-CoA) (Fig. 5A–D). The FBA still predicted 78–86% of carbon retention in the TCA cycle, but this was due to high malate dehydrogenase flux (from malate to OAA), while the cataplerotic malic enzyme flux was predicted to be low by the FBA. We attributed this difference between our  $^{13}\text{C}$ -fluxomics and the FBA modeling to the low resolution of the anaplerosis-cataplerosis node in the FBA algorithm (Supplementary Data 4).

With respect to relationships between our  $^{13}\text{C}$ -fluxomics and proteomics data, there was a general trend of positive correlation between changes in protein abundances and changes in fluxes in cataplerosis, anaplerosis, 4 reactions in gluconeogenesis, and at least 7 reactions in the TCA cycle (Fig. 5E). However, due to the discrepant magnitudes in the respective protein abundance changes and flux changes, there was an overall poor 1:1 correlation (Pearson correlation,  $r = 0.11$ – $0.35$ ,  $P = 0.08$ – $0.59$ ) (Fig. 5E). For instance, although carbon flux through isocitrate dehydrogenase increased 5-fold to 8-fold during growth on the phenolic acids compared to SUC, there was less than 2-fold change in the enzyme abundance. Serine phosphorylation was previously implicated in modulating flux through isocitrate dehydrogenase in *P. putida* KT2440 grown on a glucose:benzoate mixture versus glucose alone<sup>41</sup>. The discrepancy between changes in enzyme abundance and metabolic fluxes in our correlation matrices were thus consistent with the proposal that metabolic fluxes in central carbon metabolism are driven primarily by thermodynamic factors and post-translational modifications<sup>41,61</sup>.

To examine consequences of the remodeled metabolic network on cofactor balance, we determined the rates of production and consumption of NADPH, NADH/UQH<sub>2</sub>, and ATP during the catabolism of the phenolic substrates compared to SUC, as a reference (Fig. 6A). Due to reported absence of flux through oxPPP during gluconeogenic growth<sup>48</sup>, as illustrated in Fig. 1A and confirmed by our  $^{13}\text{C}$ -fluxomics illustrated in Fig. 5A–D, cofactor production through oxPPP was not a contributing factor in our cofactor balancing for phenolic acid metabolism. Furthermore, water-forming NADH oxidase was not included in the cofactor balancing, based on a previous report of its minimal to no impact on metabolic flux distribution in *P. putida* KT2440<sup>42</sup>. Increased flux through cataplerosis via malic enzyme and through isocitrate dehydrogenase in the TCA cycle led to 1.2-fold to 2.5-fold greater NADPH production in cells grown on phenolic substrates compared to SUC-grown cells (Fig. 6A). As a result, the NADPH production was 24–44% in excess of the NADPH demand for both biomass synthesis and the peripheral pathway for aromatic substrate catabolism, including formaldehyde detoxification; this NADPH surplus was routed to NADH synthesis through transhydrogenase reactions (Fig. 6A). Due to the promoted retention of carbon flux in the TCA cycle, NADH/UQH<sub>2</sub> production was 1.4-fold to 2.7-fold higher during catabolism of phenolic substrates relative to SUC utilization (Fig. 6A). The NADH surplus was

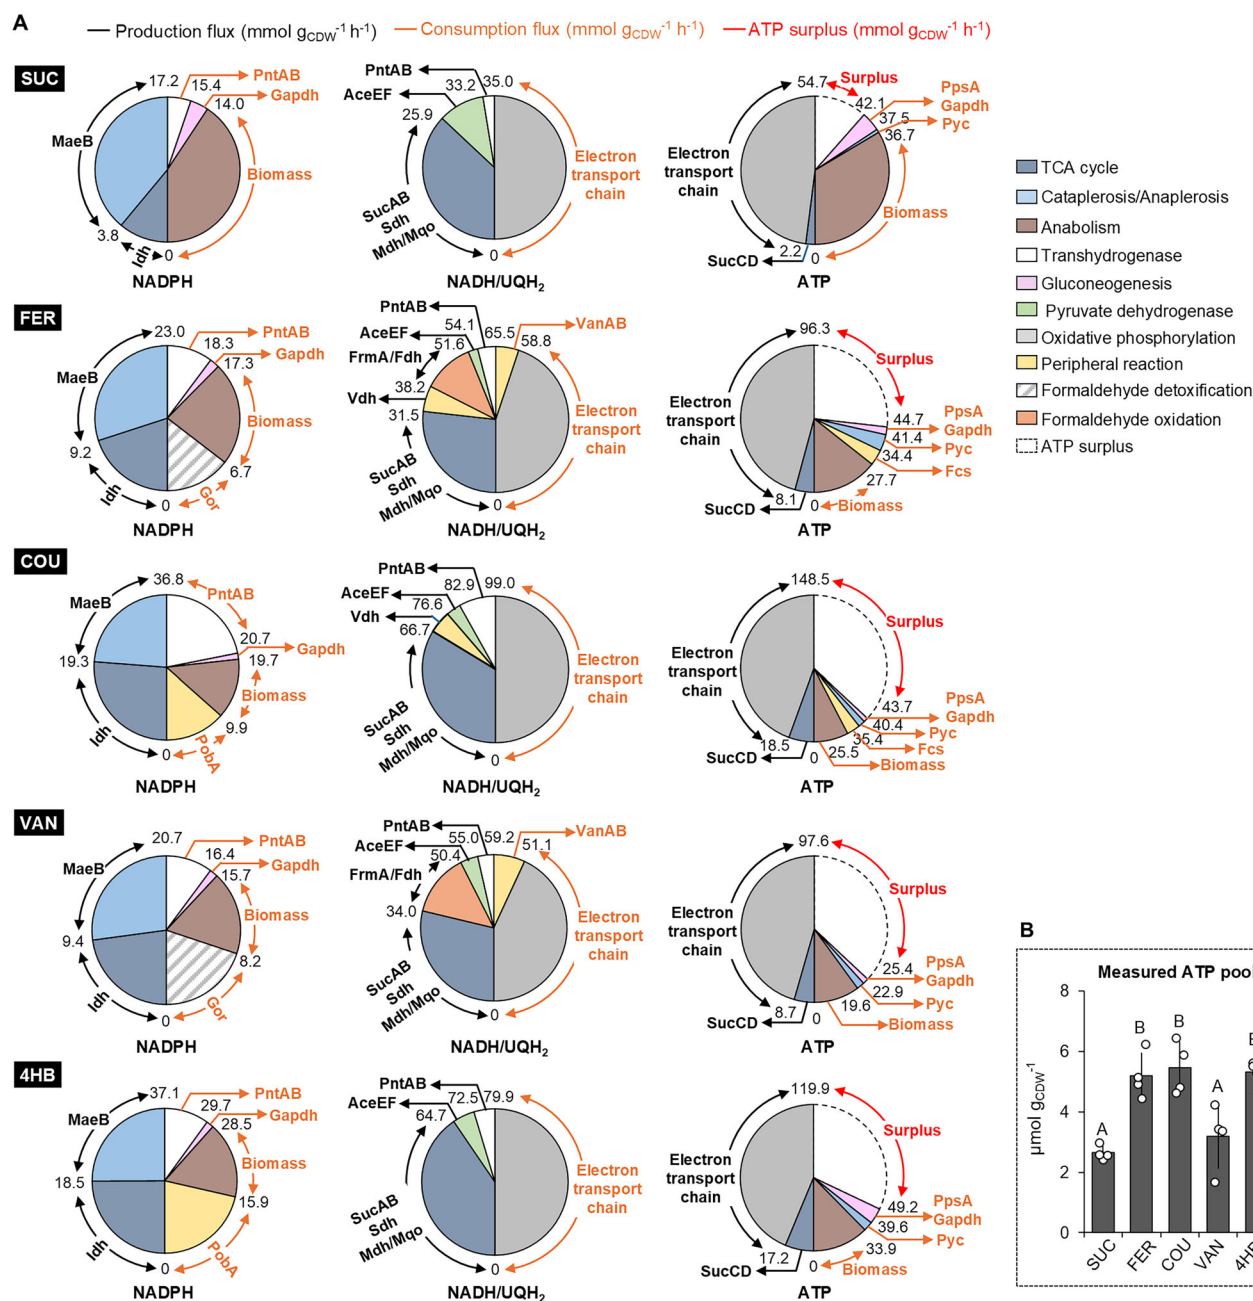

**Fig. 5 | Quantitative flux analysis of the reaction network in phenolic acid metabolism revealed structure of the cataplerosis-anaplerosis nodes to sustain high flux in the TCA cycle.** Metabolic flux analysis of *P. putida* KT2440 grown on A FER, B COU, C VAN, and D 4HB as the sole carbon source constrained by proteomics, metabolite pool sizes, and <sup>13</sup>C metabolomics data. E Correlation matrices of relative flux changes versus relative protein abundance changes. All fluxes are normalized to the substrate uptake rate ( $q$ ). The weight of arrows is relative to flux magnitude. Relative flux changes between cells grown on the phenolic

substrates and SUC are denoted by a blue-black-red color scheme. Increased flux is shown in shades of red, decreased flux is shown in shades of blue, and black indicates negligible differences in flux values. The yellow arrows represent fluxes that are predicted to be only in phenolic acid catabolism. The gray arrow represents metabolite secretion. Flux model of *P. putida* grown on SUC is provided in SI, Fig. S6. The complete flux estimations are provided in Supplementary Data 3. Abbreviations of metabolites are the same as shown in the main text.

1.4-fold to 2.7-fold higher in phenolic substrate-fed cells than SUC-grown cells, resulting in a corresponding fold increase in ATP production via oxidative phosphorylation (Fig. 6A). In corroboration of the model-predicted ATP surplus, absolute quantitation of the intracellular ATP

content revealed up to 2-fold higher ATP in cells fed with FER, COU, or 4HB than in the SUC-fed cells ( $P < 0.01$ ); the lack of similar trend with VAN implied unaccounted ATP demand, likely related to additional ATP needed to cope with oxidative stress during VAN assimilation<sup>62</sup> (Fig. 6A, B). The

**Fig. 6 | Quantitative mapping of metabolic reactions in cofactor flux balancing during processing of four lignin-derived phenolic acid substrates compared to succinate. A** Production (black) and consumption (orange) fluxes ( $\text{mmol g}_{\text{CDW}}^{-1} \text{h}^{-1}$ ) of NADPH, NADH/UQH<sub>2</sub>, and ATP during growth on, from top to bottom, SUC, FER, COU, VAN, and 4HB. **B** Quantified intracellular ATP pool size ( $\mu\text{mol g}_{\text{CDW}}^{-1}$ ) in cells grown on the lignin-related phenolic substrates compared to succinate. In **A**, the numbers of the pie chart indicate the flux values ( $\text{mmol g}_{\text{CDW}}^{-1} \text{h}^{-1}$ ); the metabolic proteins and pathways involved in each reaction are

specified near the pie charts and in the color legends, respectively. In **A**, production of ATP from NADH/UQH<sub>2</sub> was calculated using a phosphate to oxygen (P/O) ratio of 1.5. Details of flux data in **(A)** were provided in SI, Table S6. Data in **B** are expressed as mean  $\pm$  standard deviation from four independent biological replicates ( $n = 4$ ) and one-way ANOVA was performed followed by Tukey's HSD post hoc test; statistically significant differences ( $P < 0.05$ ) are denoted by a change in letter. Detailed data in **(B)** were provided in SI, Table S1.

surplus of ATP predicted by the flux model, which was confirmed by independent measurements of intracellular ATP, was consistent with the relatively higher energy charge values during processing of the phenolic substrates compared to SUC (SI, Fig. S2), underscoring the optimization of the carbon metabolism in *P. putida* to maintain a high-energy state during phenolic substrate utilization.

## Discussion

The catabolism of lignin-derived phenolic substrates represents a critical step in valorizing lignin using biotechnologically relevant microbes<sup>2–4</sup>.

Strains of *P. putida* are extensively studied for this endeavor due to their native ability to catabolize various aromatic compounds<sup>6</sup>. However, elucidation of the native metabolic network in relation to cofactor balance in *P. putida* during catabolism of phenolic substrates remains a knowledge gap. Here, we performed a comprehensive quantitative analysis of the metabolic underpinnings of carbon and energy fluxes in *P. putida* KT2440 during conversion of two hydroxycinnamates and two hydroxybenzoates, which represent common lignin-derived phenolic substrates.

To address metabolic bottlenecks during conversion of phenolic substrates, increase in enzyme expression was shown to be a successful strategy

when an enzyme (i.e., VanA or VanB) exhibited a preference for NADH over NADPH, but bottleneck was not alleviated for an enzyme (i.e., PcbA) with NADPH specificity due to cofactor deficiency<sup>17,21,29,32</sup>. The latter deficiency was circumvented by substituting for an enzyme with broader cofactor specificity (i.e., PraI) or by increasing NADPH supply through substrate co-feeding<sup>30,32</sup>. Our quantitative flux analysis determined that the metabolic fluxes generated excess in both NADPH and NADH in *P. putida* KT2440, but the NADH surplus was up to 6-fold higher than the NADPH surplus. Thus, our findings implied that the native cofactor balance was more amenable to buffering increased NADH demand than increased NADPH demand from enzyme overexpression. These findings inform rational design of metabolic engineering strategies, particularly when targeting fluxes through isoenzymes with similar catalytic functions but with distinct cofactor preferences. The surplus of NAD(P)H can benefit bio-production of free fatty acids<sup>63</sup> and polyhydroxyalkanoates<sup>64</sup>, while ATP overproduction can be employed in improving yield of biopolymers that require energy input, such as  $\epsilon$ -Poly-L-lysine<sup>65</sup>. Predicted by our proteomics data and confirmed by <sup>13</sup>C-fluxomics, we identified key nodes of flux remodeling with important energetic consequences during the metabolism of the phenolic substrates. At the cataplerosis-anaplerosis nexus between the TCA cycle and gluconeogenesis, we found that *P. putida* KT2440 exhibited the specific cataplerotic routing of carbon fluxes through malic enzyme (to deplete malate and produce pyruvate) and anaplerotic routing through pyruvate carboxylase (to replenish OAA). Notably, the enhanced carbon flux through malic enzyme was critical in sustaining the necessary NADPH yield, but resulted in decreasing flux to OAA through malate dehydrogenase. As a consequence, one important role of the anaplerotic carbon recycling to the TCA cycle via pyruvate carboxylase was to satisfy OAA demand for biosynthesis. This adaptation of cataplerosis and anaplerosis generated 50% of the NADPH yield and sustained high flux through the TCA cycle to produce over 70% of the NADH yield, which eventually fueled oxidative phosphorylation for ATP production. A similar routing of carbon fluxes through the cataplerosis-anaplerosis nodes was noted in glucose-grown *P. putida* to satisfy elevated cofactor demands in response to oxidative and energetic stresses<sup>41,47</sup>. For instance, in response to oxidative stress, *P. putida* has been shown to enhance carbon flux from glucose catabolism through the oxPPP to generate excess NADPH that exceeded 50% of the biomass demand<sup>47</sup>. Moreover, when the conversion of NADH to ATP via oxidative phosphorylation was uncoupled chemically in glucose-fed *P. putida*, there was an increase in carbon flux through the high-energy producing side of the TCA cycle towards providing NAD(P)H and ATP production to counterbalance the metabolic perturbation<sup>42</sup>. Thus, we propose that cofactor-driven metabolic reprogramming is a widespread phenomenon under different substrate utilization.

The *ortho*-cleavage pathway, the only known catabolic route for the phenolic substrates in *P. putida* (particularly strain KT2440), generates SUC and acetyl-CoA to feed into the TCA cycle. There are two other reported aerobic PCA cleavage pathways: for example, the 2,3-*meta* cleavage pathway found in *P. putida* strains mt-2 and H, and the 4,5-*meta* cleavage pathway revealed in *Comamonas testosteroni* and *Sphingobium* sp. SYK-6<sup>61,66–69</sup>. The 2,3-*meta* cleavage route generates pyruvate and acetyl-CoA with the production of NADH<sup>66,69</sup>; the 4,5-*meta* cleavage route generates OAA and pyruvate with the production of NADPH<sup>61,68</sup>. The quantitative analysis employed here to decode cofactor balance involved in the *ortho*-cleavage pathway could be used to evaluate the metabolic routing of phenolic carbons and cellular cofactor balance following the other cleavage pathways.

In sum, we unraveled quantitatively the interplay between carbon metabolism and energy metabolism in *P. putida* KT2440 grown on lignin-derived phenolic acid substrates, focusing on the catabolism of hydroxycinnamates and hydroxybenzoates with PCA as the common catabolic intermediate. Lignin-derived compounds can also constitute of other aromatic structures<sup>5</sup>, with different intermediates such as catechol and gallate<sup>6</sup>. Moreover, sugar monomers and aliphatic acids often co-exist with phenolic acids in hydrolysates of lignocellulosic feedstocks<sup>70,71</sup>. Therefore, a valuable next step is the investigation of the energy metabolism in *P. putida* during

co-utilization of different phenolic structures with sugars or aliphatic acids. To this end, the current research findings provide a valuable quantitative blueprint of the native metabolic network and its tuning of carbon and energy fluxes for further interrogations and explorations of *Pseudomonas* and other related bacterial platforms for lignocellulose valorization.

## Methods

### Bacterial cultivation

*P. putida* (strain KT2440) was obtained from the American Type Culture Collection (ATCC) and stored in Lysogeny broth (Miller) nutrient-rich medium with 25% glycerol at  $-80^{\circ}\text{C}$ . Cells were washed and inoculated from frozen stocks into 20-mL glass tubes that contained 5 mL of pH-adjusted (7.0) minimal nutrient medium with the same carbon-equivalent concentration, 100 mM C, of each substrate as a sole source of carbon: FER, COU, VAN, 4HB or SUC. The minimal nutrient medium contained 5.0 mM  $\text{NaH}_2\text{PO}_4$ , 20 mM  $\text{K}_2\text{HPO}_4$ , 37 mM  $\text{NH}_4\text{Cl}$ , 17 mM  $\text{NaCl}$ , 0.81 mM  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , and 34  $\mu\text{M}$   $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ . Addition of essential trace metal nutrients and  $\text{FeSO}_4$  (30  $\mu\text{M}$ ) to the nutrient medium was done prior to inoculation. After initial inoculation of the culture in glass tubes at  $30^{\circ}\text{C}$  with shaking at 220 rpm overnight in an incubator-shaker (New Brunswick Scientific, Edison, NJ)<sup>48</sup>, the cells were harvested, washed and subsequently transferred into 125-mL or 250-mL baffled flasks. To optimize oxygen transfer, only one-fifth of the volume of the baffled flask was filled with the minimal nutrient medium with carbon source. Cell growth was monitored by measuring the optical density at 600 nm ( $\text{OD}_{600}$ ) using an Agilent Cary UV-Vis spectrophotometer (Santa Clara, CA). Cell dry weight per gram ( $\text{g}_{\text{CDW}}$ ) was measured by weighing the mass of lyophilized cell pellets collected throughout the growth<sup>48</sup>. The conversion factor of  $\text{OD}_{600}$  and  $\text{g}_{\text{CDW}}$  was calculated through linear regression with  $R^2$  coefficient greater than 0.80<sup>48</sup>. All growth experiments were conducted in three biological replicates.

### Mutant construction

Construction details for strains, oligonucleotides, and plasmids are detailed in SI, Tables S7–S9. In brief, all plasmids were synthesized and cloned by Twist Biosciences. Ribosome binding sites were optimized for each native *P. putida* KT2440 sequence<sup>72</sup>. For the construction of *P. putida* strains, the parental strain *P. putida* AG5577 containing a total of nine unique *attB* sites was used<sup>73</sup>. The parental strain *P. putida* AG5577 was confirmed to be identical to the wild-type *P. putida* KT2440 in phenolic acid utilization (SI, Fig. S2). All integrations were achieved by serine recombinase-assisted genome engineering using either the BxB1 or TG1 recombinase<sup>73,74</sup>. Integrations were confirmed using Oxford Nanopore sequencing at Plasmidsaurus (<https://www.plasmidsaurus.com>).

### Measuring extracellular substrate depletion

Aliquots of cell suspensions were collected and spanned at different time points throughout biomass growth. Following filtering during centrifugation (Costar Spin-X, 0.22- $\mu\text{m}$ -pore-size filter), the filtrates were stored at  $-20^{\circ}\text{C}$  until analysis. The concentration of each aromatic substrate was determined using ultra-high-performance liquid chromatography (UHPLC) with an Agilent ZORBAX Eclipse Plus C18 column ( $4.6 \times 100$  mm with 5  $\mu\text{m}$  particle size) and a UV detector at 210 nm for 4HB and VAN detection, and 275 nm for FER and COU detection. The injection volume was 10  $\mu\text{L}$  and the column was maintained at  $25^{\circ}\text{C}$ . The mobile phase consisted of 0.1% formic acid (eluent A) and 80:10:10 acetonitrile:methanol: $\text{H}_2\text{O}$  (v/v) (eluent B) with a flow rate of  $0.9 \text{ mL} \cdot \text{min}^{-1}$ . The gradient of eluent B was set as 0 min, 6%; 6.5 min, 15%; 8.5 min, 25%; 10.75 min, 37.5%; 15.5 min, 65%; 16.25 min, 6%. Extracellular substrate depletion rate, in  $\text{mmol g}_{\text{CDW}}^{-1} \text{ h}^{-1}$ , was determined by regression analysis. The rate of SUC depletion was obtained by Wilkes et al.<sup>48</sup>.

### Quantitative proteomics

*P. putida* KT2440 was cultured until mid-exponential phase ( $\text{OD}_{600} = 1.0$ – $1.2$ ) using 100 mM C of FER, COU, VAN, 4HB, or SUC as the sole carbon source in the nutrient minimal medium. After centrifugation of

2-mL cultures ( $10,000 \times g$  for 5 min at 4 °C), the cell pellets were washed twice with phosphate-buffered solution (pH = 7.4) within 10 min to remove extracellular components followed by quenching with cold methanol (4 °C) and incubated on ice for 30 min<sup>75</sup>. Samples were kept on ice to minimize protein change during the processing. The quenched cell suspensions were centrifuged, and the pellets were resuspended in methanol and stored at −80 °C until analysis.

The samples were processed with an on-filter in-cell (OFIC) digestion approach<sup>76</sup>. Briefly, after transferring the samples to E3 filters (CDS Analytical, Oxford, PA), and centrifuging ( $400 \times g$  for 1 min), the filter was washed once with methanol, and treated with 10 mM Tris(2-carboxyethyl)phosphine and 40 mM chloroacetamide (in 50 mM triethylammonium bicarbonate, TEAB), followed by incubating at 45 °C for 10 min. The sample-containing filters were spun to remove liquid, followed by washing once with 50 mM TEAB. Subsequently, the samples were digested with Trypsin/LysC mix at 37 °C for 16–18 h. After digestion, the peptides were eluted, pooled, and dried in SpeedVac. The peptides were desalted with StageTips (CDS Analytical, Oxford, PA), dried, and stored at −80 °C until further analysis.

The peptides were first loaded onto a trap column (PepMap100 C18, 300  $\mu\text{m} \times 2 \text{ mm}$  with 5  $\mu\text{m}$  particle size; Thermo Scientific) then separated through an analytical column (PepMap100 C18, 50  $\text{cm} \times 75 \mu\text{m}$  with 3  $\mu\text{m}$  particle size; Thermo Scientific) with eluents consisting of 0.1% formic acid in water (v/v) (eluent A) and 0.1% formic acid in acetonitrile (v/v) (eluent B) with a flow rate of 250  $\text{nL} \cdot \text{min}^{-1}$  using an Ultimate 3000 RSLCnano system with nano electrospray ionization for liquid chromatography mass spectrometry analysis (LC-MS). The MS data were acquired on an Orbitrap Eclipse mass spectrometer with FAIMS Pro Interface (Thermo Scientific) at 120 K resolution, followed by MS/MS acquisition in data-independent mode following a FAIMS-DIA proteomic pipeline<sup>77</sup>.

The mass spectrometry data were processed using Spectronaut software (version 19.1)<sup>78</sup> and a library-free DIA analysis workflow with directDIA+ and the *P. putida* KT2440 protein sequence (Uniprot 2024 release; 5950 sequences). In short, the settings for Pulsar and library generation included: Trypsin/P as specific enzyme; peptide length from 7 to 52 amino acids; allowing 2 missed cleavages; toggle N-terminal M turned on; Carbamidomethyl on C as fixed modification; Oxidation on M and Acetyl at protein N-terminus as variable modifications; FDRs at PSM, peptide and protein level all set to 0.01; Quantity MS level set to MS2, and cross-run normalization turned on. Bioinformatics analyses were performed using Perseus software (version 1.6.2.3)<sup>79</sup>. The full dataset of proteomics is provided in Supplementary Data 1.

### Intracellular metabolite levels and isotope labeling kinetics

To profile the intracellular metabolites of each of the substrate condition (100 mM C of FER, COU, VAN, 4HB, or SUC), cell suspensions (3 mL) of *P. putida* KT2440 during mid-exponential growth phase ( $\text{OD}_{600} = 1.0\text{--}1.2$ ) were filtered (0.22  $\mu\text{m}$  nylon membranes; Whatman, 7402-004), then lysed in a cold solvent (4 °C) containing methanol, acetonitrile, and water in a 2:2:1 (v/v) ratio. Metabolism was quenched by submerging the filter containing the cells immediately in the cold solvent mixture, which lysed the cells; there was less than 1 min between the filtering process and the transfer of the filter to the cold solvent. This well-established protocol<sup>80</sup> for metabolite extraction after quenching metabolism was illustrated previously by the senior author<sup>41,48,60,61,81,82</sup> and others<sup>83–85</sup>. The suspensions with the lysed cells were centrifuged ( $10,000 \times g$ , 4 °C for 5 min) and aliquots (200  $\mu\text{L}$ ) of the supernatants in 2 mL-tubes were dried under ultrapure nitrogen gas followed by storage at −80 °C before further analysis. The dried samples, collected from four biological replicates, were resuspended in 100  $\mu\text{L}$  LC-MS grade water before metabolomics analysis.

In preparation for kinetic <sup>13</sup>C-labeling experiments, 3-mL exponentially-growing *P. putida* KT2440 cells (two transfers, three biological replicates) on each unlabeled substrate (100 mM C of FER, COU, VAN, 4HB, or SUC) were filtered (0.22  $\mu\text{m}$  nylon membranes; Whatman, 7402-004), and the filters containing the cells were placed onto agar plates containing 100 mM C of the same substrate, followed by incubation at 30 °C until

exponential growth was resumed. To initiate <sup>13</sup>C-labeling of intracellular metabolites, cell-containing filters were transferred onto fresh agar plates with 50% of <sup>13</sup>C-labeled substrate: <sup>13</sup>C<sub>6</sub>-phenyl-FER, <sup>13</sup>C<sub>6</sub>-phenyl-COU, <sup>13</sup>C<sub>6</sub>-phenyl-VAN, <sup>13</sup>C<sub>6</sub>-phenyl-4HB, or U-<sup>13</sup>C<sub>4</sub>-succinate. These labeled substrates were purchased from Cambridge Isotopes (Tewksbury, MA) or Sigma-Aldrich (St. Louis, MO). At four different time points (15 s, 1 min, 5 min, and 15 min), cells adhered to the filter were quenched into the aforementioned cold quenching solution (4 °C); data for time 0 were obtained with cells directly quenched from the unlabeled plate. The quenched cell suspensions were processed following the aforementioned nitrogen drying procedure and the extracted metabolites were stored at −80 °C until metabolomics analysis.

### Metabolomics analysis

Intracellular and extracellular metabolites were quantified based on our established metabolomics protocol using UHPLC (Thermo Fisher Scientific Dionex UltiMate 3000) coupled with high-resolution mass spectrometry (Thermo Fisher Scientific Q Exactive quadrupole-Orbitrap) operating in negative mode<sup>48,81</sup>. The LC column, an Acquity UPLC BEH C18 Column (particle size 1.7  $\mu\text{m}$ , 2.1  $\text{mm} \times 100 \text{ mm}$ , Waters), was maintained at 25 °C with an injection volume of 10  $\mu\text{L}$ . The eluents contained 97:3 (v/v) LC-MS grade water:methanol with 15 mM acetic acid and 10 mM tributylamine (solvent A) and methanol (solvent B)<sup>81</sup>. The flow rate was set at 0.18  $\text{mL} \cdot \text{min}^{-1}$ . The data was analyzed on the Thermo Scientific XCalibur software (v3.0) using a series of standard concentrations. The fraction of different isotopomers was analyzed using the Metabolomic Analysis and Visualization Engine software version 2011.6.17<sup>86</sup>; to correct for the natural abundance of <sup>13</sup>C, IsoCor v2.2.0<sup>87</sup> was used. The full dataset of kinetic <sup>13</sup>C-metabolomics is provided in Supplementary Data 2.

### <sup>13</sup>C-fluxomics analysis

We employed both the levels and the kinetic isotopic profiling of intracellular metabolites to perform an isotope non-steady state metabolic flux analysis (INST-MFA)<sup>37</sup>. A core *P. putida* metabolic network was constructed based on published resources with modifications to supplement aromatics utilization pathways<sup>46,49</sup>. The biomass yield equation was modified from a previous genome scale model for *P. putida* KT2440<sup>88</sup>. The INCA software (v2.3) based on the Matlab platform<sup>89</sup> was used to simulate isotopomer balances when *P. putida* was fed on different aromatic substrates and succinate. The INST-MFA models were constrained with growth, substrate consumption and metabolite secretion rates, measured pool sizes (CIT, AKG, SUC, PYR, PEP, 3PG, G6P, AcCoA) and kinetic isotopomer distributions (CIT, AKG, SUC, OAA as aspartate, PEP, PYR, 3PG, DHAP, G6P, S7P, AcCoA). Flux estimations were reiterated at least 50 times from random initial values. At least three independent flux estimations were performed for each INST-MFA model to ensure the flux estimations were consistent. The estimates were considered as statistically acceptable fits when the results passed the  $\chi^2$  goodness-of-fit test (cutoff 95% confidence level), i.e., the minimized variance-weighted sum of squared residuals (SSR) were within the expected range. The standard errors (95% confidence intervals) of the flux estimations for the reactions in the central carbon metabolism were calculated through the Monte Carlo simulation module associated with the INCA software<sup>49,89</sup>. Complete flux estimations are in Supplementary Data 3. Cofactor balance was calculated from quantified fluxes for metabolic reactions with production or consumption of NADPH, NADH/UQH<sub>2</sub>, and ATP. Only NADH was included for vanillate O-demethylase because VanB was shown to prefer NADH over NADPH<sup>17</sup>.

### Flux balance analysis

The most recent genome-scale model of *P. putida* KT2440 (iJN1463) was downloaded from the BIGG database (<http://bigg.ucsd.edu/>)<sup>88</sup>. The FER, VAN, and 4HB catabolic reactions are present in the original iJN1463 model. The COU uptake and initial catabolic reactions to coumaroyl-CoA were added manually to the model. The optimized flux distribution predicted by FBA was performed using the COBRApy library (version 0.29.1)<sup>90</sup>.

Substrate uptake rates for SUC, FER, COU, VAN, and 4HB were fixed at the experimentally determined values (in mmol/g<sub>CDW</sub>/h), which are 16.0, 6.7, 9.9, 8.2, and 15.9, respectively. For the 4HB analysis, the PCA secretion rate was fixed at 1.2 mmol/g<sub>CDW</sub>/h as experimentally measured. Results for FBA are in Supplementary Data 4.

### Statistics and reproducibility

All experimentally measured data were expressed as mean ± standard deviation of three or four biological replicates (as indicated in figure captions). Unpaired two-tailed *t*-test was applied to evaluate the significance of differences between two groups. One-way analysis of variance (ANOVA) was used to evaluate differences among three or more conditions. Tukey's honestly significant difference post hoc test was performed for pairwise comparison in addition to one-way ANOVA. The *P* value threshold for statistically significant difference was set at 0.05.

### Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

### Data availability

Proteomics MS data are freely available via ProteomeXchange server (<https://www.proteomexchange.org/>) under accession PXD067246 and the MassIVE repository (<https://massive.ucsd.edu/>) under accession MSV000098800. Metabolomics MS data are available through the MetaboLights depository (<https://www.ebi.ac.uk/metabolights/>) under accession number MTBLS11484. All source data for the figures were provided in Supplementary Data 5, and all other data are available from the corresponding author on reasonable request.

### Code availability

Custom code for FBA analysis can be accessed through GitHub repository ([https://github.com/nqzhou/Aromatics\\_fba](https://github.com/nqzhou/Aromatics_fba)) and Zenodo repository (<https://doi.org/10.5281/zenodo.16793025>).
